

Latin America and the Caribbean (LAC) Population Database

We ask that users of this database acknowledge the source of the data with a reference to the following information:

Centro Internacional de Agricultura Tropical (CIAT), United Nations Environment Program (UNEP), Center for International Earth Science Information Network (CIESIN), Columbia University, and the World Bank (2005) Latin American and Caribbean Population Database. Version 3. Available from <http://www.na.unep.net/datasets/datalist.php3> or <http://gisweb.ciat.cgiar.org/population/dataset.htm>

Summary

The population of Latin America and the Caribbean increased from 175 million in 1950 to 515 million in 2000. Where did this growth occur? What is the magnitude of change in different places? How can we visualize the geographic dimensions of population change in Latin America and the Caribbean?

We compiled census and other public domain information to analyze both temporal and geographic changes in population in the region. Our database includes population totals for over 18,300 administrative districts within Latin America and the Caribbean. Tabular census data was linked to an administrative division map of the region and handled in a geographic information system. We transformed vector population maps to raster surfaces to make the digital maps comparable with other commonly available geographic information. Validation and error-checking analyses were carried out to compare the database with other sources of population information.

The digital population maps created in this project have been put in the public domain and can be downloaded from our website. The Latin America and Caribbean map is part of a larger multi-institutional effort to map population in developing countries. This is the third version of the Latin American and Caribbean population database and it contains new data from the 2000 round of censuses and new and improved accessibility surfaces for creating the raster maps.

Introduction

The Latin America and Caribbean Population Database project contributes to a goal of several research and development organizations to provide digital population maps for the major developing-world regions. This project follows as closely as possible the design and methodology of previously-developed Asian and African databases (Deichmann 1994, Deichmann 1996a). The database has been updated since previous versions were published on the United Nations Environment Program's spatial data clearinghouse (UNEP 2000) and on CIAT's web site. The new maps include new information from the 2000 census round for 16 countries. We improved the spatial resolution of the new map by collecting data at more detailed administrative levels for several countries, increasing the number of administrative units substantially compared to our previous release.

We include information on the sources of the population and administrative boundary data, procedures for compiling the data, and some indicators of the quality of the data set. Documentation of the methods to create the maps was derived from the earlier work for Africa and Asia. The raster population surfaces are based on a data set of over 18,300 administrative units and 10,700 populated places. Population growth rates were used to project population totals acquired at the date of each country census back to 1950 and forward to 2000. This documentation also includes appendices with information on data resolution and quality, data sources for population and administrative boundary information.

The main difference between this version and previous efforts is that it includes a mechanism that incorporates new census and administrative data as they become available, and which ensures consistency with other sources and provides easy access to the data.

Part I: Boundary and population data

I.1. Discussion of data sources

The Latin America and Caribbean administrative boundaries and population database was compiled from medium-scale maps at country and sub-national level, national population censuses and United Nations data for the smaller islands of the Caribbean. Population data for all of mainland Latin America, Cuba, Puerto Rico, Jamaica, Trinidad and Tobago, Haiti and the Dominican Republic are from population census data. Most of the administrative boundary maps for mainland Latin America and the large Caribbean islands were digitized at the International Center for Tropical Agriculture (Jones and Bell 1997). Others were acquired from government agencies in the region. The smaller island nations of the Caribbean lack sub-national administrative units. The outlines of these countries are from the Digital Chart of the World. **None**

of the input boundary or population data has been officially checked or endorsed by national statistical agencies, national geographic institutes or the United Nations.

Our work on this population mapping project progressed in parallel with the development of the Gridded Population of the World, Version 3, project (GPW3). The authors have all been involved in some aspects of GPW3 (CIESIN and CIAT, 2004). Much of the data checking for population figures was carried out in the context of the GPW3 project. Settlement points developed for GPW3 were used in the development of the accessibility model that is subsequently used to convert vector population maps to raster surfaces (CIESIN et al., 2004).

Boundaries

The scale of the source boundary maps vary from 1:50,000 to 1:1,125,000. Most of these boundaries were digitized during the 1990's from hard copy maps published in the 1980's and 1990's. In some cases, we acquired administrative division maps from national geographic institutes or from census bureaus. Users of the digital population maps should keep in mind the considerable differences in scale and quality of the input boundary maps. The quality of future boundary data should increase with improvements in capacity within the geographic and census institutes. Future efforts should rely on boundary information that is produced, verified and endorsed by the relevant agencies in each country. Appendix 4 includes more detailed information on the boundary data for each country used in the database.

In order to ensure a close match between different national maps, and to obtain maximum compatibility with other standard medium resolution data sets, all national boundaries and coastlines were replaced with the political boundaries template (PONET) of the Digital Chart of the World (DCW). The DCW is a set of basic digital GIS data layers with a nominal scale of 1:1 million scale. The use of a very detailed international boundaries template for, in some cases, relatively coarse resolution data is quite misleading, but was required to ensure a close match between the national maps. In any application, the smaller cartographic scale (i.e., coarser resolution) of the administrative boundary data in comparison to the international and coastlines template should be kept in mind.

For a few countries very detailed boundary data were available for which the spatial referencing information was not known. In light of the objectives of this project, these were nevertheless incorporated in order to achieve maximum resolution. Yet, the ad hoc transformation, projection change and rubbersheeting required to make these data compatible with the DCW template have no doubt introduced positional error which may well reach a magnitude in the order of 1-2 km.

Population data

With few exceptions, we used official census figures or official estimates, which were taken from national publications (census reports or statistical yearbooks) or from secondary data sources (yearbooks and gazetteers). The data was taken from censuses of the early 1990's or from more recent censuses near 2000. Several countries in the region have new data that is not yet publicly available. We expect to update our map when this new information becomes available. The specific sources of population data are indicated for each country in Appendix 4.

The accuracy of censuses varies by country. It was beyond the scope of this project to evaluate the accuracy of every census used, or of any of the official estimates. This would be possible since most censuses are followed by a post-census enumeration that provides an accuracy estimate. ECLAC, PRB and other sources giving country totals are likely to have values that are closer to the true value for the nation. The country totals have been corrected to account for inaccuracy in the census. Our data is from the original disaggregated censuses and does not incorporate these corrections. In countries that differed by more than 5 percent from the United Nations estimates (UN 2005), we made a uniform adjustment of the population data to bring it in line with the PRB country totals. In countries with functioning registration systems, population figures reach an accuracy within a fraction of a percent. In the US, census counts have been shown to have an accuracy of about 2 percent. With few exceptions, the accuracy of Latin American censuses is likely to be considerably lower.

Most countries in Latin America try to schedule their censuses at the beginning of a decade and at 10-year time intervals. The population data is generally from the 1990 or 2000 census rounds, with an average census date of 1996. In several cases our boundary data differed from the population data. The tabular

population data listed more administrative units than were held in the boundary maps, a problem resulting from the creation of new municipal districts since the previous census. We handled this problem on a country-by-country basis by trying to find the discrepancies and then summing the data for municipal districts that had been subdivided.

[Top](#)

1.2. Population projections and data quality

Estimation of population figures

Population projections were made on a country-by-country basis from the date of each census used to 1960, 1970, 1980, 1990 and 2000. Most of the projections were based on historical population growth rates for departments in Latin America and the Caribbean. The volume of papers and monographs on population projection methods in the demographic literature is very large. It is matched, however, by the number of publications that emphasize the continuing inability of these methods to accurately forecast population figures over more than very short time periods (O'Neill and Balk, 2001, also see the interesting discussion in Cohen, 1995).

For this project, we used ECLAC figures for population growth rates based on a mathematical trend forecast. In contrast to previous estimates for the global demography project, the current figures for each sub-national unit are based for most countries on a district-specific inter-censal growth rate between the last and the next to last enumeration. The inter-censal growth rate was calculated as

$$r = \frac{\ln\left(\frac{P_2}{P_1}\right)}{t}$$

where r is the average annual rate of growth, P_1 and P_2 are the population totals for two different time periods, and t is the number of years between the two enumerations (see, for example, Rogers 1985). The resulting growth rates were then used to derive estimates for the standard years. For example, based on enumerations in 1967 and 1977 and a corresponding rate r , the 1970 population would be calculated as:

$$P_{1970} = P_{1967} \cdot e^{3r}$$

In cases where no data were available for a year before 1960 or after 2000, the trend between the two closest enumerations was used to extrapolate the earliest or latest available data. Similarly, simple trend forecasts beyond 2000 could be made using the average growth rates between 1990 and 2000 as reflected in the figures in the GIS database.

For predictions over only a few years, mathematical trend projections are usually fairly accurate, and the specific type of function used has little influence on the results (Cohen 1995). A more elaborate estimation approach such as the cohort survival method would result in more reliable estimates, but the data requirements for this technique (age and sex distribution as well as age specific birth, death and migration rates) were far beyond what was possible in this project. Given the method used for the population forecasting, the characteristics of the available source data have a significant impact.

The population estimates are at best a rough estimate which should be interpreted within wide confidence margins. In general we can expect the reliability of the estimates to be lower, the longer the census upon which they are based lies back - that means the confidence intervals around the point estimates become increasingly wider over time. The data for some countries for which data were available for the early eighties only, need to be regarded as a best-guess only.

The figures included in the database are directly taken from the estimation and thus show more significant digits than is justified by their accuracy. During data manipulation and processing one should preserve all

significant digits, but for presentation purposes, the figures should be rounded to reflect the uncertainty of the data. Even the use of population numbers to the nearest thousand in the above table is clearly optimistic.

Given the limited amount and quality of the base population data, we checked the resulting total national population figures against standard benchmarks, the regularly published population estimates produced by the UN. Obviously, the data are by themselves associated with a considerable amount of uncertainty since the estimates are based on conditional forecasts that make a number of assumptions regarding the most recent and future fertility, mortality and migration rates. They are also based, for the most part, on official census figures which sometimes prove to be highly unreliable. In cases where our estimate was considerably different from the UN estimate, the intercensal growth rates were adjusted uniformly such that the resulting estimate was equal to or close to the UN estimate (United Nations 1998). Typically this is the case where the latest available population figures were very old, or where a country experienced significant reductions in fertility in recent years that are not sufficiently reflected in the population dynamics between the last two censuses. The adjustments are indicated in the specific country documentation (Appendix I).

Several exceptions were made to our general use of the ECLAC population growth rate data to make population projections. In the case of the 16 countries where we had new 2000 census round data, projections for the last decade were calculated at the level of the available data - usually municipio level. We used ECLAC growth rate data to make projections for the larger islands -- Cuba, Jamaica, Puerto Rico, Trinidad and Tobago, Haiti and the Dominican Republic. The United Nations population projections (at the national level) were used for all the smaller Caribbean countries in our database where we lack sub-national boundary data (United Nations 1998). In a few additional cases we used national level population growth rates for the projections. United Nations population figures were used to calculate population growth rates in three cases:

- for Puerto Rico prior to 1990 where we had no information on population growth rates at sub-national levels;
- for Surinam and Guyana where census figures were available for only one point in time or the next to last census was too long ago, we applied the average annual national growth rate for a ten-year period centered on the target date. This modification resulted in a uniform adjustment of population figures across these two countries;
- for departments in Latin America with missing population growth rate data in the ECLAC database. This group included departments in Argentina (1), Brasil (2), Colombia (5), Cuba (1), Honduras (1), Mexico (1), Paraguay (4), and Venezuela (1).

Data quality estimates

Given our limited knowledge about the accuracy of the input data, it is impossible to make an objective assessment of data quality. The development of a qualitative index of boundary and population data quality was considered. However, such an index would be associated with considerable subjective judgment. Any question of "how good are the data?" is incomplete since we also have to ask "for what purpose?" Data that are clearly inappropriate for high resolution applications at the province or sub-province level, are still sufficiently accurate to be used in regional or continental scale applications (the prime motivation for this project), or for the visualization of spatial patterns in a country. Thus, we only provide some informal summary measures in the table below, and refer to the individual country documentation that provides all known details about the lineage of the data (admittedly, this knowledge is too often very limited). The user can consider this information to make his or her own decision about whether the data are appropriate for the specific tasks.

As in previous databases of this nature, we included two useful summary measures of data resolution in the summary table in the appendix:

$$\text{Mean resolution in km} = \sqrt{\frac{\text{country area}}{\text{number of units}}}$$

i.e. the length of a side of an administrative unit, if all units were square. And

$$\text{Mean population per unit} = \frac{\text{total national population}}{\text{number of units}}$$

These two measures complement each other. In countries where large areas are uninhabitable, the mean resolution in km gives a biased impression of available detail. In such cases, the number of people per unit is a more meaningful indicator. The following table shows how these measures of resolution compare for Africa, Asia and Latin America.

Continent	Mean resolution in km	Mean population per administrative unit ('000)
Asia	117	1148
Africa	16 (32) ¹	7 (28) ¹
Latin America and the Carribean	33	29

¹ Figures in parentheses indicate the values when South Africa (83,000 units) is discounted from the total of 109,268 units in Africa

There are 18,318 administrative units with population information in the data set. Much of the reduction of resolution in kilometers for Latin America and the Caribbean is due to the high level of detail for Brazil, with about one third of all the units for the data set. The population data for all the countries of Latin America was collected at a finer level of detail. The reduction in mean population per unit reflects the higher resolution in kilometers, and in comparison with Asia, lower population densities.

[Top](#)

Part II : Raster data

The Latin America and Caribbean data set was prepared with similar design and methodology as that of the Africa and Asia data set previously developed (Deichmann 1994, Deichmann 1996a). The global demography project at NCGIA produced a gridded data set for the whole world which was constructed using a smoothing technique that has the property of preserving population totals within each administrative unit (Tobler et al. 1995). The raster surfaces based on the approach outlined in the following section were constructed using an alternative interpolation method. This method preserves population totals in each district as well and incorporates additional information on settlements, transport infrastructure and other features important in determining population distribution. The conversion of population data from a vector or polygon representation to raster format has the added advantage that the data can be more easily combined with many spatially referenced physical data sets which are most often stored in a gridded format. The raster format facilitates the use of these data in research and policy analysis and will hopefully contribute towards an increasingly integrated approach to the study of problems related to population, the environment, economics and culture as advocated, among others, by Cohen (1995). The approach outlined here as well as alternative approaches to spatial population modeling are discussed in more detail in Deichmann (1996b).

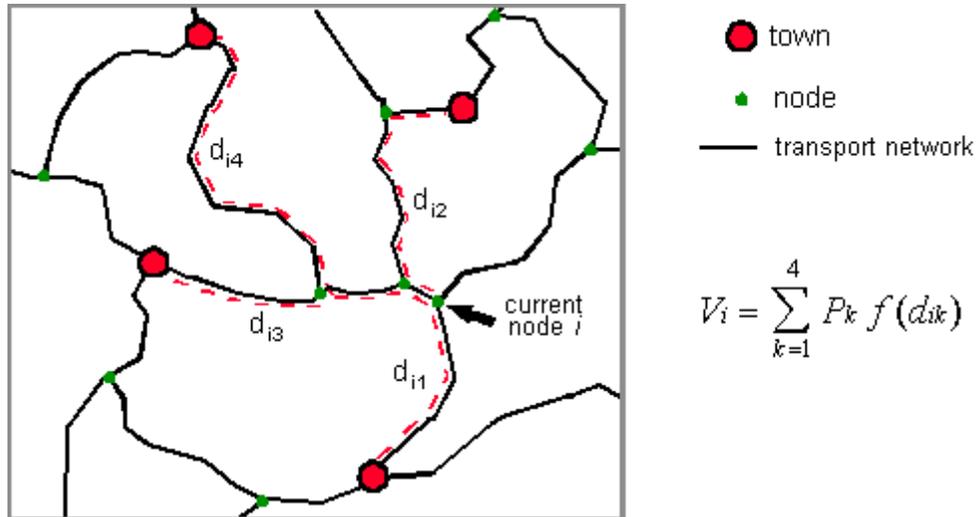

II.1. Gridding approach

The basic assumption upon which the construction of population distribution raster grids for Latin America and the Caribbean is based is that population densities are strongly correlated with accessibility. Accessibility is most generally defined as the relative opportunity of interaction and contact. These opportunities are the largest where people are concentrated and transport infrastructure is well developed.

Within any given area, we therefore expect a larger share of the known total population to live in more accessible regions compared to areas that are less well connected to major urban centers.

Summary description of the method

The method for the development of population raster grids consists of the following steps. The most important input into the model is information about the transportation network consisting of roads, railroads and navigable rivers. The second main component is information on urban centers. Data on the location and size of as many towns and cities as can be identified are collected, and these settlements are linked to the transport network. This information is then used to compute a simple measure of accessibility for each node in the network. The measure is the so-called *population potential* which is the sum of the population of towns in the vicinity of the current node weighted by a function of distance, whereby network distances rather than straight-line distances are used. The following figure illustrates the computation of the accessibility index for a single node.

The computed accessibility estimates for each node are subsequently interpolated onto a regular raster surface. Raster data on inland water bodies (lakes and glaciers), protected areas and altitude are then used to adjust the accessibility surface heuristically. Finally, the population totals estimated for each administrative unit (as described in the first part of this documentation) are distributed in proportion to the accessibility index measures estimated for each grid cell. The resulting population counts in each pixel can then be converted to densities for further analysis and mapping. Each of these steps will now be described in more detail.

Construction of the transportation network

There are few data sources that provide consistent, geographically referenced base data layers for large areas such as an entire continent. The transportation infrastructure data for this project was constructed using the following data sets: roads and railways from the Digital Chart of the World (DCW) and major navigable waterways from the World Boundary Databank II (WBDII). WBDII originated at the U.S. Central Intelligence Agency and an Arc/Info version is available from the Environmental Systems Research Institute (ESRI). The nominal scale of WBDII is 1:3 million. The scale of the DCW base maps (the Operational Navigational Charts) is 1:1 million. Since we also used DCW for the international boundaries in the administrative unit data layers and since WBDII and DCW appear to share common ancestors, a good fit exists between the individual data layers.

The road dataset was improved by including road type characteristics from a range of paper and digital maps. Roads were identified as follows.

Road type	Total length in km (and as a % of all roads)	Estimated travel speed (kmph)

Primary (Motorway/Major road)	304,500 (22%)	60
Secondary (All weather/Improved)	300,000 (21%)	35
Tertiary (Partially improved/Earth roads)	802,000 (57%)	25
Other network types		
Railroads	120,000	40
Navigable rivers	265,000	10
Auxillary arcs	1,690,000	5

A brief technical discussion is now required to clarify the structure of the transportation data. After merging the individual components of the transport network into one data layer there are still no connections between the individual components (e.g., roads and rivers). To allow the model to choose the most efficient means of transport at any point in the network, the intersections between the individual transport layers need to be found. This is a standard GIS operation that results in a well-structured data layer of *arcs* (or *links*) representing roads or rivers. These are connected by *nodes* which are intersections of two or more arcs of different or similar types. Nodes, of course also represent the end of an unconnected arc.

The program used for calculating accessibility produces an estimate for each node in the network. The problem in an application where the network is sparse in many regions is that no values are derived for areas that are not connected to the network. Also, DCW only includes fairly important transport features that are relevant at a cartographic scale of 1:1 or 1:3 million. One solution is to calculate the accessibility index for the center of each grid cell of the subsequently generated output raster. From each grid cell, the distance to the closest transport feature could be calculated and added to the network distances to the closest towns. This approach was used by Geertman and van Eck (1995).

However, this approach is not realistic where the closest access point to the transport network is at a location which is actually far away from urban centers. Another network access location may be further away from the grid cell initially, but better connected to major towns. To evaluate different options of network access for each grid cell would be impractical, and we therefore chose a different approach. In areas where the transport network is sparse, auxiliary arcs were added which could be thought of as "feeder roads". Essentially, this implies that people who may be living in these remote areas are using trails or tracks to get to the main transport network first and then continue their travel to the nearest city along the fastest routes. The algorithm automatically determines which network access is optimal in minimizing overall travel times.

It would be straightforward to use simple network distance for the calculation of accessibility. However, different arcs representing various transportation modes are associated with quite different travel speeds. For example, a kilometer travel on a paved road will take much less time than the same distance on a river. Instead of simple distance, we therefore used cumulative travel time as the weight in the accessibility calculation. Each arc in the resulting complete transportation network is associated with an estimate of average travel speed that is thought to be possible. Primary roads were assumed to allow for a travel time of 60kmph, secondary roads were assigned a speed of 35kmph, and tertiary roads were assigned a speed of 25kmph. 40kmph were used for railroads, 10kmph for navigable rivers, and 5kmph for the auxiliary network access routes. For each arc, we calculated the real-world distance in kilometers.

All data layers are referenced in geographic (latitude/longitude) coordinates and no map projection is able to represent real-world distances in all directions with sufficient accuracy for large regions. We therefore calculated the correct length of each arc as the sum of the great-circle distances of all individual segments that make up the arc between two nodes. The time it takes to traverse each section of the transport network is then simply its length in km divided by the travel speed associated with the specific mode of transport.

Setting up urban data

The accessibility index is the sum of the population totals of the towns in the vicinity of the current location weighted by the network travel time ("distance") to those towns. Data on the location and size of urban centers were provided by CIESIN and accounted for 10,700 cities with population estimates for year 2000.

Towns need to be connected to the transport network to enable the accessibility calculation algorithm to find the closest towns for each node in the network. Each settlement was therefore assigned to the network node closest to its recorded location.

Run accessibility calculation

For the actual accessibility calculation we used a stand-alone program written in the C programming language. This program reads the entire network definition which consists of (a) the identifiers for each node and the population size of the town that corresponds to the node - zero in most cases, indicating that no town is located at the node -, and (b) the identifiers of the two nodes that define each arc and the travel time required to traverse the arc.

A further option of the program that allows for considering the direction of travel along an arc was not used. This implies that there are no "one-way streets" and that travel time is the same regardless of which way one travels. This assumption could be relaxed since, for example, travel speeds are lower up-river than down-river, but the added gain in realism will not compensate for the additional effort required in defining these details. Also, no further assumptions are made about modal choice. In moving through the network, an imaginary traveler may change his or her means of transport at will. This is unrealistic since a switch, say from road travel to a train and on to a boat, are all associated with delays. Even so, in order to keep the model simple (and run-times manageable) we did not introduce a penalty for switching the transport mode. A modification relevant to an application in a regional setting was made, however. For any arc that crosses an international boundary, the travel time was increased by 30 minutes reflecting delays in border crossings. This added travel time could be varied depending on the relations between two neighboring countries. This would either require subjective judgment or very detailed information on the permeability of international borders.

For each node in the network, the program now finds the network path to each of a specified number of towns that results in the lowest overall travel time. In the initial program specification, all towns reached within a user-defined specified travel time (e.g., 5 hours) were determined. However, in areas where towns are sparsely distributed and the number of nodes and arcs is large, this resulted in unacceptably long run-times. Instead, we modified the program to find the closest four towns or less if fewer than four towns were accessible within a more generous threshold travel time. This also makes the index somewhat more comparable across large areas, since the previous specification resulted in the accessibility index for some densely urbanized areas to be based on fifty or more towns, while other regions would only contain two or three.

For the shortest path calculation the program uses the standard Dijkstra algorithm. The program section used for this search consists of a modified version of a fast implementation of this algorithm developed by Tom Cova, a transportation GIS specialist at NCGIA. The Dijkstra algorithm evaluates the network structure around the current location starting from the center and reaching out further and further. For applications in which only one origin-destination pair is of interest, this is inefficient and various modifications have been suggested to speed up the search. In this application, in contrast, the interest is in finding the shortest path to all towns within the vicinity and the Dijkstra's "shortcoming" is actually a bonus. The slightly modified algorithm thus "collects" towns as it ventures out from the originating node. Once four towns have been found and the program has determined that all additional connected arcs will not lead to a town that is closer than those already found, the search is terminated and the town populations and travel times are passed to a program section that calculates the accessibility measure.

This measure is the sum of the town populations weighted by a negative exponential function of travel time ("distance"), i.e.

$$V_i = \sum_{k=1}^{k=n} P_k \cdot e^{(-d_{ik}^2/2\alpha^2)}$$

where V_i is the accessibility estimate for node i , P_k is the population of town k , d_{ik} is the travel time/distance between node i and town k , and α is the distance to the point of inflection in the distance decay function. This parameter was set to one hour in this case which means that the influence of a town one hour away decreases to about 60 percent, and a town two hours away will only contribute 14 percent of its total population to the accessibility index. Rather than using total urban population, we applied a square root transformation to the population figures, implying that each additional person living in a city has an increasingly lower influence. This transformation avoids an exaggerated influence of very large mega-cities while being less of an equalizer than the more common log-transformation.

Interpolation

The accessibility index that is available for each of the nodes in the network needs to be converted into a regular raster grid. We used a simple inverse distance interpolation procedure that resulted in a relatively smooth surface. A problem with this technique is that interpolated values will not fall outside the range of the values recorded at the neighboring node locations. In analogy to interpolating elevation data: if recorded values are available only for locations on the slope of a mountain but not at the peak, the interpolated value for the summit location will be underestimated. Conversely in our application, if values are recorded only for network nodes, but not for areas that are remote from transport routes (e.g., deserts), then using the neighboring node values for interpolation will overestimate the accessibility for the remote location.

Yet, experiments with other interpolation procedures did not result in satisfactory results. Thin plate spline interpolation may be more appealing theoretically since it would allow values at interpolated locations to fall below (or above) those that are recorded at neighboring locations if the overall tension surface suggests a corresponding trend. However, the values estimated for some locations were clearly out of the range of what would be reasonable. Given the large number of nodes introduced in remote areas by adding the auxiliary access routes, we consider the simple inverse distance interpolation to be sufficiently accurate.

Adjustment of the accessibility measure

Three additional data sets were used to adjust the resulting accessibility index grid: inland water bodies, protected areas, and elevation. Lake areas were masked and grid cells that fell onto a glacier were assigned an accessibility value of zero. This information was derived from the DCW lakes layer.

GIS data layers on protected areas were obtained from the World Conservation Monitoring Center (WCMC). Unfortunately, little information about each protected area was available besides its name, such that it was impossible to relate, for example, protection status to an estimate of how much the areas may still be used and inhabited by people. We reduced the accessibility index for grid cells that fell into national parks to 20 percent of the original value. These values are subjectively determined to allow for the fact that the protection of protected areas is not always perfect. Since most of these parks are in remote region, the change in predicted population densities that would be introduced by varying the adjustment factors should be small.

Areas higher than 5000 m were masked out of the analysis. Many of these areas in the Andes lack protected area status, but are uninhabited. We made no adjustment to areas below 2000 m. Between 2000 and 5000 m we weighted the accessibility measure with higher areas having less accessibility. Several major cities in the Andes are above 2000 meters but at increasingly higher elevations population density markedly drops.

[Top](#)

Distribution of population

The distribution of the population total available for each administrative unit over the grid cells that fall into that unit is straightforward. The accessibility values estimated for each grid cell serve as weights to distribute population proportionately. First the grid cells in the accessibility index are summed within each district. Each value is divided by the corresponding district sum such that the resulting weights sum to one within each administrative unit. Multiplying each cell value by the total population yields the estimated number of people residing in each grid cell. The standardization of the accessibility index implies that the absolute magnitudes of the predicted access values are unimportant - only the variation within the administrative unit determines population densities within each district.

Again, we have to take account of the fact that all GIS data layers and raster grids are referenced in latitude/longitude coordinates. This means that grid cells further away from the equator represent a smaller real-world area than grid cells close to it. For example, a 2.5 minute grid cell has a real-world area of 10.8 square km at 60 degrees latitude, of 18.6 square km at 30 degrees and of 21.4 square km at the equator. We therefore weighted the accessibility index value for each grid cell by the actual area of the grid cell before standardizing the values within each district.

Because only the relative magnitudes of the accessibility index are important in distributing total population, and since most administrative units are fairly small, the error introduced by the distortions of the geographic coordinate system will usually be insignificant. However, in areas where the available resolution of the administrative units is fairly low, the difference in the actual areas of grid cells within a district that are located further away from the equator compared to those closer to the equator can be relatively large. For example, in LAC which reaches into much higher latitudes than Africa, the resulting difference in predicted population densities using undadjusted and adjusted accessibility values reached up to eight people per square km. From the grid cells of total population, population density images are created by dividing the population counts estimated for each grid cell by the real-world area in square km of that cell.

Evaluating the accuracy of this interpolation method is difficult in the absence of very high resolution population data (e.g., by enumeration areas) that could be used as a benchmark. For the Asian database a simple experiment was conducted in which state level population figures for India were interpolated. The total population allocated to each district could then be compared to the actual district figures. The differences are acceptable in relatively homogeneous regions but are obviously quite large in areas where population distribution is very scattered such as in high mountain or desert regions. The same results could be expected for Africa. The model will work better, the more detailed the administrative data, the more urban population figures are available, and the more homogeneous the population is distributed.

Appendices

A.1. Illustrative example of the stability of population estimates

For Israel, population figures were available for a number of years in the *Statistical Yearbook of Israel 1991*. The following table shows the total population for the six districts of Israel for four recent years. The last three columns show total population estimates for 1995 based on average annual growth rates between each of the first four years and 1990. The choice of the growth rate obviously has a considerable effect on the resulting estimate. Even allowing for the special nature of Israel's population dynamics due to the country's immigration policy (the most likely explanation for the high 1989-90 rates), the fact that the estimates are strongly dependent on the available input data becomes clear.

District	Total population (‘000) ¹				Average annual percentage growth rate			Resulting estimates (‘000) for 1995 based on rate for

A.3. Attribute item definitions

Polygon Attribute Table		
Position	Item	Description
17	SQKM	Area of the polygon
21	ADMSQKM	Area of the admin unit (sum of SQKM)
25	CODE	L-Land, IS-Island, IW-Inland Waterbody
28	ADMINID	Administrative Unit ID (see below)
32	COUNTRY	3-Letter ISO Country ID
35	NAME1	Name of first subnational level unit
60	NAME2	Name of second subnational level unit ('N.A.' if not available)
85	NAME3	Name of third subnational level unit ('N.A.' if not available)
110	NAME4	Name of fourth subnational level unit ('N.A.' if not available)
135	NAME5	Name of fifth subnational level unit ('N.A.' if not available)
160	DEMOFLAG	1 for the major polygon belonging to the admin unit, 0 elsewhere (see below)
162	P60	Total estimated population 1960
166	P70	Total estimated population 1970
170	P80	Total estimated population 1980
174	P90	Total estimated population 1990
180	P00	Total estimated population 2000
Arc Attribute Table		
29	FEATURE	0 - International Boundary 1 - Boundary of first level unit 2 - Boundary of second level unit 3 - Boundary of third level unit 9 - Boundary with "outside polygon"

ADMINID - consisting of

3-digit UN country code + 2-digit first level unit code + 2-digit second level unit code + 2-digit third level unit code + 2-digit fourth level unit code + 2-digit fifth level unit code.

To produce the subnational code, the administrative units were (a) sequentially numbered based on a list of administrative units in an official census publication if available, or (b) alphabetically ordered otherwise.

DEMOFLAG - indicates the major (i.e., biggest) polygon in cases where an administrative unit consists of more than one polygon. For all polygons belonging to the same unit, the full attribute information is replicated in the data table. Therefore, for any frequency table construction or summary statistics calculation, one needs to select the polygons with a FLAG value of one first to avoid double counting.

Acknowledgments

The International Center for Tropical Agriculture ([CIAT](#)) supported the development of administrative and population databases for Latin America and the Caribbean through their Geographic Information Systems laboratory and the Land Use project. Silvia Elena Castaño, Rosalba Lopez, Alexander Cuero, Carlos Nagles, Elizabeth Barona and Peter Jones developed many of the foundation data sets used in this project. We

thank Liliana Perez for her work to verify the quality of the database. We are grateful for the cooperation of the United Nations Economic Commission for Latin America (ECLAC), the World Bank and all the countries of Latin America and the Caribbean that supported this effort. This version of the database was made in close cooperation with the Center for International Earth Science Information Network's (CIESIN) Gridded Population of the World, Version 3 project. The The Inter-American Development Bank (IADB), United Nations Environment Program (UNEP/GRID Sioux Falls , UNEP/GRID Arendal), the World Resources Institute (WRI), and the International Food Policy Research Institute (IFPRI) provided funding and support throughout the development of this project.
